

Two-centre shield law vs. measurement in S_{10} (23,988,173 twin centres): own modular-shift gain $\times$ cross-prime hedge

For $6\Delta N = 42$ the hedge is < 1 (the gap's shift makes the right centre collide more often at $q = 5$); for 210 the hedge is > 1 . Both predicted by measured modular distributions, closing to $\leq 1.5\%$.
